

C++ POLYMORPHISM

C++ Function Overloading

- As we know that functions are the piece of code that can be used anywhere in the program with just calling it multiple times to reduce the complexity of the code.
- In POP, we can use as many functions as per need, however, the names of the function shouldn't match.
- In the case of OOP, we can use a function name as many times following the condition that the number of arguments or the type of arguments must differ.
- So the method of using the same function name for different functions is simply called **function overloading**.
- When an overloaded function is called from main program the function with matching arguments is invoked.

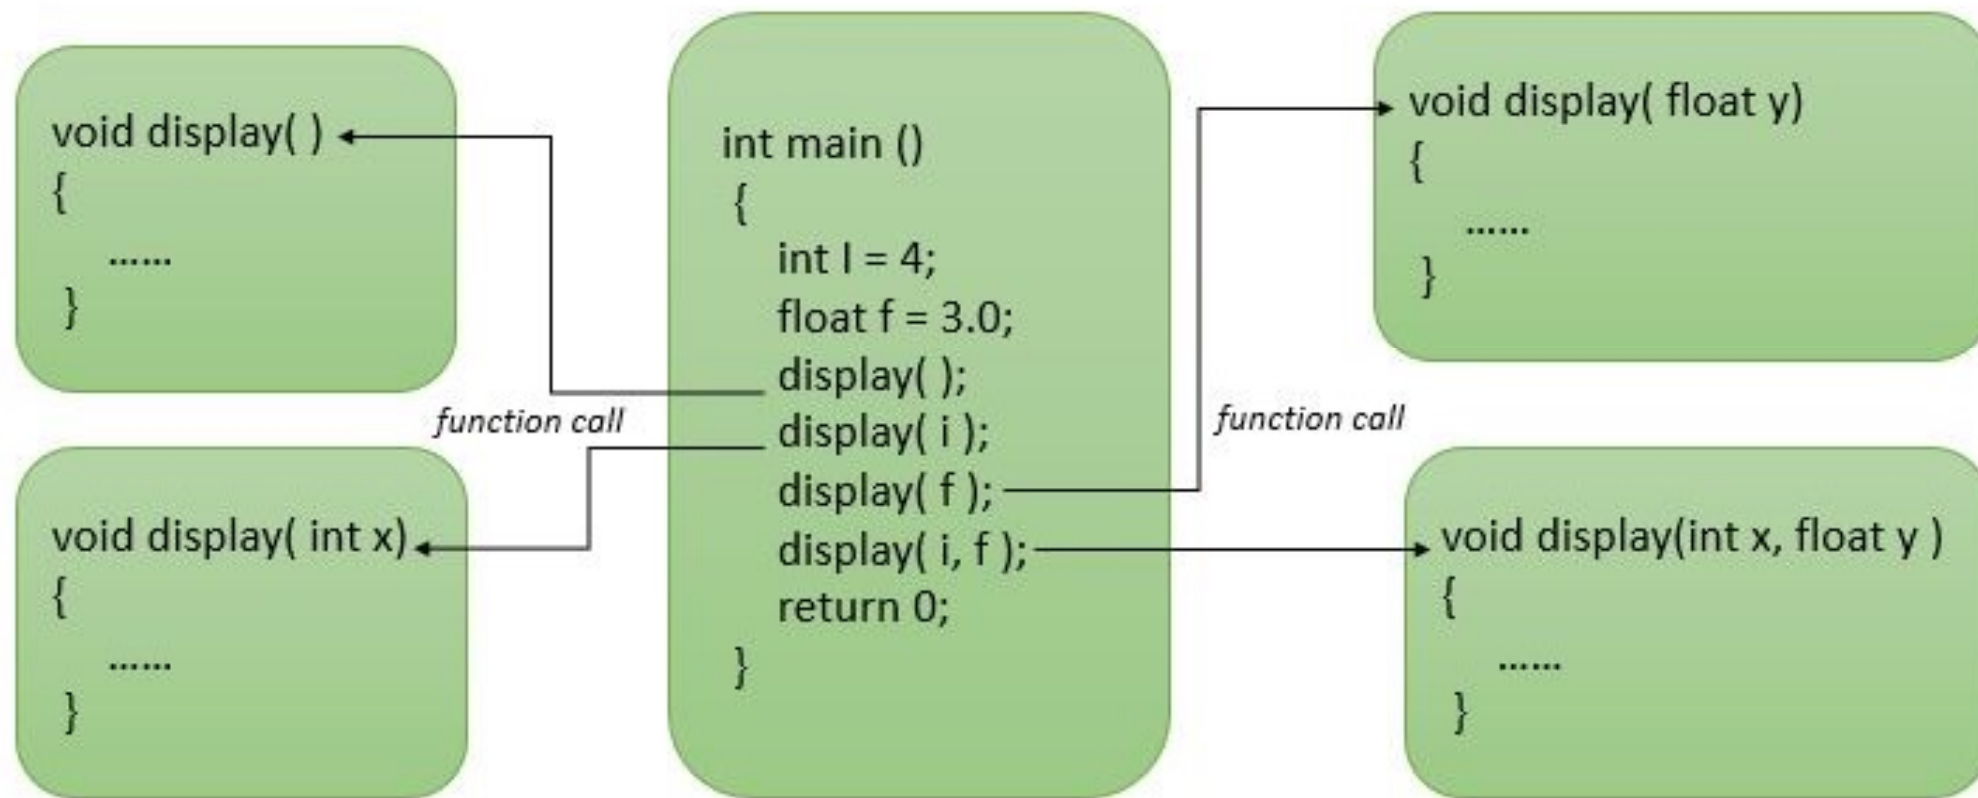

Examples

`void display();` `//function with no arguments`

`void display(int);` `//function with one integer type arguments`

`void display(float);` `//function with one floating point arguments`

`void display(int, float);` `//function with one floating and one integer type arguments`

```
#include <iostream.h>
```

```
void display ( )
```

```
{
```

```
int a = 3;
```

```
cout << a << endl;
```

```
}
```

```
void display (int a )
```

```
{
```

```
cout << a << endl;
```

```
}
```

```
void display (double a )
```

```
{
```

```
cout << a << endl;
```

```
}
```

```
void display(int a, float b)
```

```
{
```

```
cout<< a << " , " << b << endl;
```

```
}
```

```
int main()
```

```
{
```

```
display();
```

```
display(5);
```

```
display(2.3);
```

```
display(5,4.0);
```

```
getch();
```

```
}
```

C++ Function Overriding

- As we know, inheritance is a feature of OOP that allows us to create derived classes from a base class.
- The derived classes inherit features of the base class.
- Suppose, the same function is defined in both the derived class and the based class.
- Now if we call this function using the object of the derived class, the function of the derived class is executed.
- This is known as **function overriding** in C++.
- The function in derived class overrides the function in base class.

```
#include <iostream>
using namespace std;

class Base {
public:
    void print() {
        cout << "Base Function" << endl;
    }
};

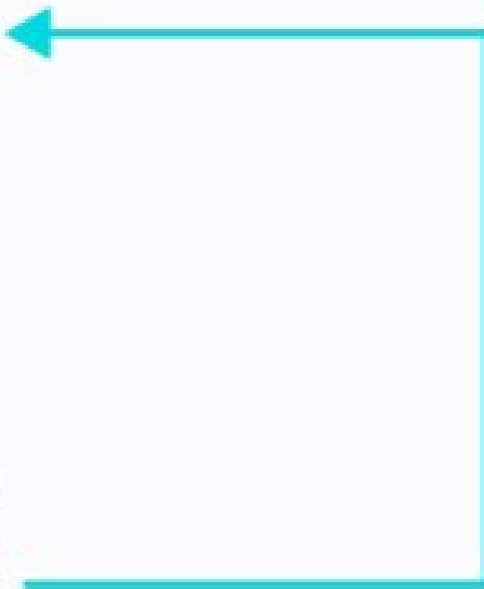

class Derived : public Base {
public:
    void print() {
        cout << "Derived Function" << endl;
    }
};
```

```
int main() {
    Derived derived1;
    derived1.print();
    return 0;
}
```

Output

Derived Function

```
class Base {  
    public:  
        void print() {  
            // code  
        }  
};  
  
class Derived : public Base {  
    public:  
        void print() {  
            // code  
        }  
};  
  
int main() {  
    Derived derived1;  
    derived1.print();  
    return 0;  
}
```

A diagram consisting of a red line that starts from the `derived1.print();` line in the `main()` function, extends horizontally to the right, then vertically upwards, and finally horizontally to the left, ending with an arrowhead pointing to the `void print() {` line inside the `Derived` class definition. This illustrates the resolution of the method call to the derived class's implementation.
